Mineral wool is mainly used for thermal insulation of building parts and of pipelines, as well as for sound absorbers. Other names for the material are rock wool, stone wool or man-made vitreous fibers (MMVF). As these names indicate, it consists of tiny mineral fibers with typical diameters between 6 and 10 µm. It is produced by spinning molten rock at about 1600°C. In order to obtain the final shape of the mineral wool product, an appropriate organic bonding agent is added to the fiber network.

The investigation of mineral wool using Micro-X-ray fluorescence spectroscopy (Micro-XRF) in the scanning electron microscope (SEM) and energy-dispersive spectroscopy (EDS) is especially promising through the combination of trace element and light element sensitivity with spatial resolution. This is demonstrated in the following example.

Fig. 1 shows a photograph of the two investigated mineral wool specimens from different manufacturers.
**Measurement conditions**

Measurements were performed with the micro-focus X-ray source XTrace mounted on a FE-SEM. XTrace is equipped with a Rh-target X-ray tube and with an X-ray optics focusing the X-rays onto a spot of about 50 µm diameter on the specimen. X-ray tube operation conditions were 40 kV high voltage and 600 µA beam current.

Only a few fibers of each sample were fixed on a thin polyester foil. Mounting small and thin specimens on thin foils reduces the spectrum background considerably and improves the detection limit. Fig. 2 shows the SEM specimen holder with a few fibers on the foil.

**Results**

Fig. 3 displays the SEM image of fibers taken from the specimen on the left side in Fig. 1. The SEM image of the specimen in Fig. 1 right is very similar, i.e. both specimens are very difficult to discriminate only by their SEM images.

The XRF spectra clearly reveal the difference in composition of the two investigated mineral wools. Especially significant is the difference in the titanium content. The sulfur line is caused by the glue on the foil.

The spectra in Fig. 4 were measured with the X-ray source focused on fiber bundles as shown in Fig. 3, with a count rate of approx. 2 kcps.

Single fibers can also be analyzed. Using the effect that the foil is charged by the X-ray beam, which results in a dark spot in the SEM image, an individual fiber can be selected simply by moving the specimen stage while observing this...
element Si. Elements K, Ti and Mn are not visible in the EDS spectrum at all, the Ca and Fe peaks are very low.

With a 30 mm² XFlash® 6 SDD mounted on the SEM the count rates collected from a single fiber were more than sufficient to acquire a line scan across the fiber using the unique stage line scan option of the ESPRIT software.

Fig. 5 Secondary electron (SE) image at low magnification and low voltage of 2 kV, showing a long fiber. The dark spot in the center of the image is caused by the X-ray beam.

Fig. 6 SE image of a single fiber at 2 kV beam voltage and high magnification.

Fig. 7 Comparison of XRF (red) and EDS (blue) spectrum of the fiber shown in Fig. 5. The peaks not labeled in the red spectrum are spurious peaks, S from the foil and a broad peak caused by scattered tube radiation.
This line scan is shown in Fig. 8. Of course, a considerable broadening is observed giving an impression for the spatial resolution that can be currently achieved with the micro-focus X-ray source.

This discrimination would not have not been possible with EDS alone. A proper specimen mounting, in this case fixing fibers on a few micron thick polyester foils, to attain low background and high detection sensitivity, is very important for such investigations. The same mounting method can be applied as well to acquire individual X-ray spectra of other small particles.

The radiation power (photon flux) of the used X-ray source together with the high collection efficiency of a large area SDD even enable the measurement of an X-ray spectrum of a single fiber, even though the spot size is around 50 µm in this case. A smaller spot size with the inevitable drawback of reduced photon flux is not necessary to collect spectra of individual or sufficiently separated objects.

Additionally, the superior sensitivity for mid-range to heavy elements of XRF invites to analyze the specimens in detail beyond the scope of this application note. That is, to determine the sum of oxide concentrations Na₂O, K₂O, CaO, MgO and BaO, as prescribed by the European Commission Directive 97/69/EC. This directive determines the maximum content of these oxides for the fibers to be considered non-hazardous.

**Conclusion**

The combination of EDS and Micro-XRF to investigate fiber structure and composition of mineral wool has turned out to be a very useful method. Due to the excellent spatial resolution and the sensitivity it was easy to distinguish the mineral wool specimens by their chemistry, although their optical appearance is almost the same. A discriminator is – for instance – the height difference of their Ti peaks.
