

Micro-XRF Back to the Roots – Part V

The speakers

- Falk Reinhardt, falk.reinhardt@bruker.com
- Senior Application Scientist,
Bruker Nano Analytics, Berlin, Germany

- Dr. Roald Tagle, roald.tagle@bruker.com
- Head of XMP Application,
Bruker Nano Analytics, Berlin, Germany

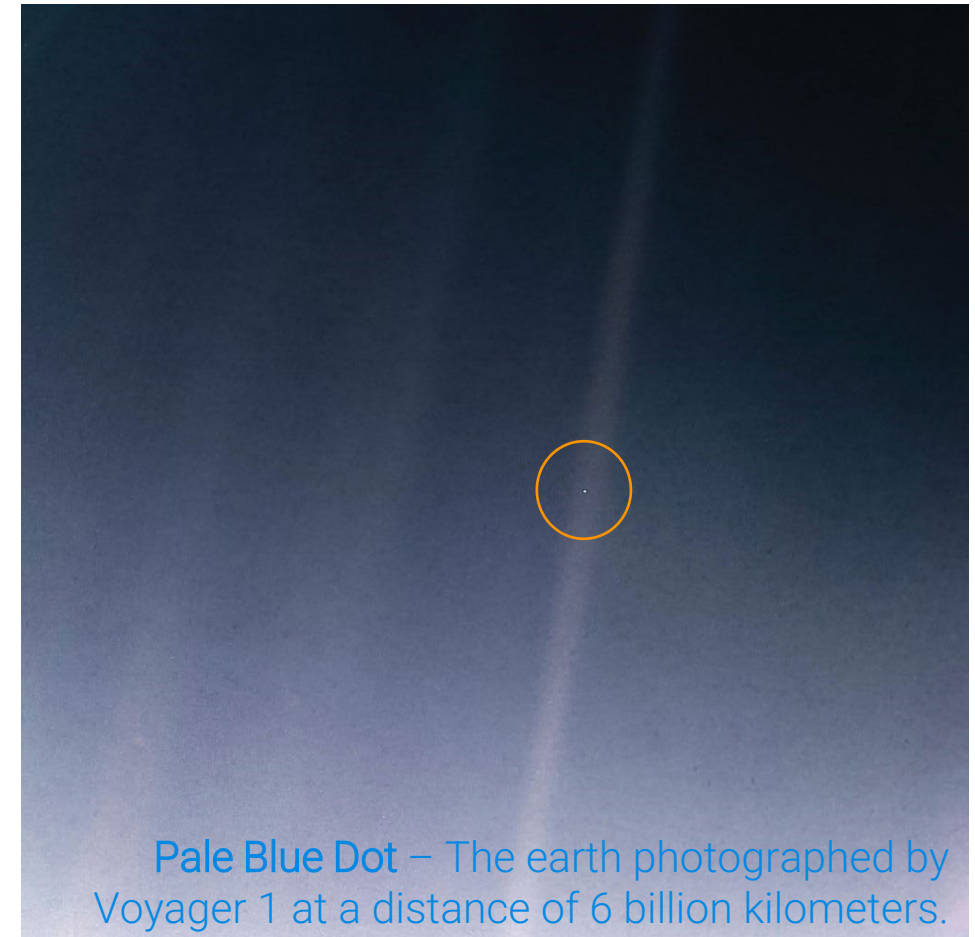

Overview

- **Part I** of this series introduced micro-XRF as a technique and gave an overview of the individual components.
- **Part II** focused on qualitative micro-XRF analysis, showing how much information can be gained without knowing the composition of a sample.
- **Part III** discussed quantitative XRF analysis already, focusing on the range of application.
- **Part IV** introduced micro-XRF on the SEM, showing where this secondary excitation allows to extend the analytical capabilities.
- **Part V** shall show that today XRF quantification does not have to be based on standards anymore.
 - Which samples can be quantified and what to expect from quantification?
 - What is the difference between standard-based and (standard-supported) FP quantification?

Setting the scene

What is a homogeneous sample?

- When looking from far away, everything looks homogeneous. Planet earth, for example, looks pale blue. Only when getting closer large-scale inhomogeneities, like water versus land are revealed.
- On the other end, not even the atoms themselves are homogeneous. They have inner structure, created by different sub-atomic particles.
- Ultimately, the sample homogeneity depends on how close a look we take, i.e. what **analytical technique** we use to assess it.
- So what is homogeneity and why do we bother?

Pale Blue Dot – The earth photographed by Voyager 1 at a distance of 6 billion kilometers.

Setting the scene

Why does homogeneity matter?

- The earth's surface is made from 71 % of water and only 29 % of landmass. ...and luckily we are not inhabitants of a homogeneously muddy planet.
- So the heterogeneity may be a sample property that we need to know to truly understand that sample.
- Sometimes, of course, we only need to know a general number, that we can use to compare one sample to the next. (Jupiter weighs 318 times as much as Earth)
- So not only the measurement method, but also our **analytical question** dictates, whether we can assume the sample to be homogeneous or not.

Setting the scene

Sample and analytical method

- Some samples **are homogeneous**.
- Some samples **appear homogeneous**, because the analytical method cannot resolve the inhomogeneities or averages over all individualities.
- Some samples **can be considered homogeneous**, because the possible level of heterogeneity wouldn't affect the answer to our analytical question.
- ...and there are the other cases:
 - The method cannot resolve inhomogeneities, but the sample is too heterogeneous to give “good results”.
 - The analytical question itself is about the (in)homogeneity of the sample.
- Some methods can analyse a wide variety of samples and/or answer very different analytical questions.
- In general, the analytical method should match both, the analytical question and the sample!

Setting the scene

Homogeneity and Quantification

- When a heterogeneous sample is investigated with a method that can resolve the respective heterogeneities, individual parts of the sample can be analyzed independent of each other.

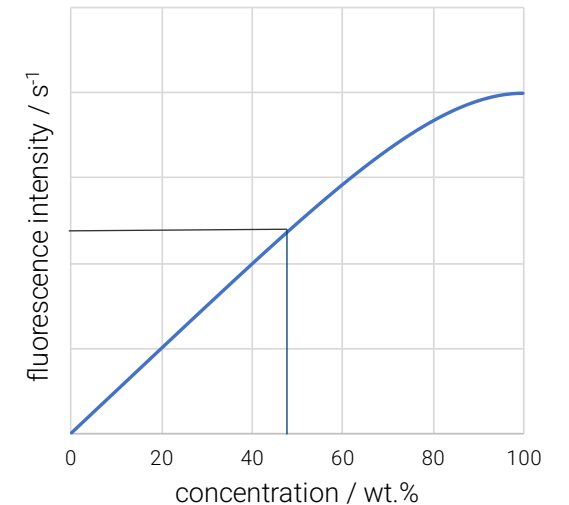

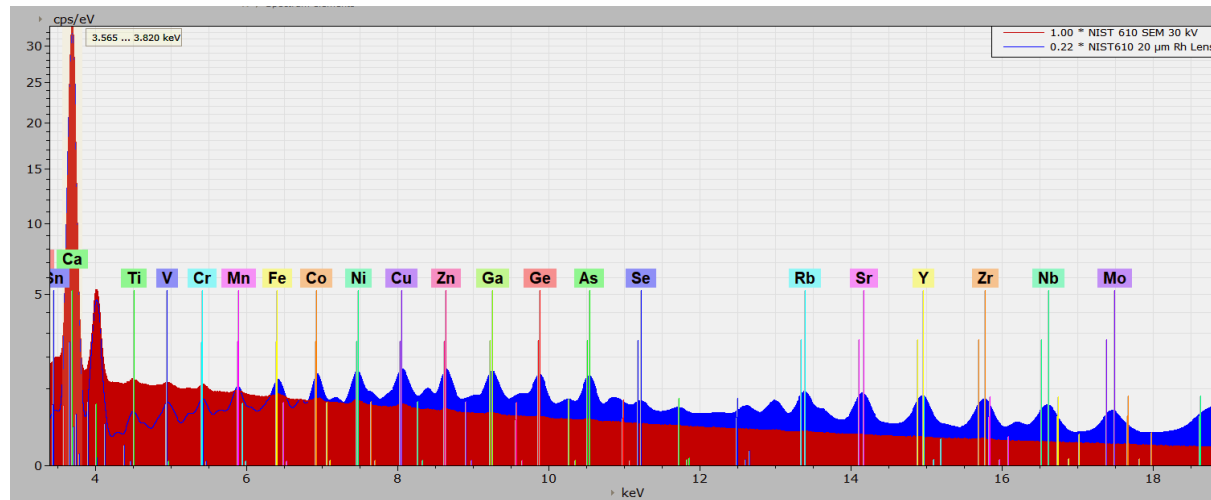

- With XRF we determine element abundance as the sample property of interest.
- Micro-XRF resolves lateral structures down to 20 μm .
- The X-ray information can be obtained from depths up to some Centimeter!
- Depending on the matrix, the analytical volume is between 20 μm^3 and 200 μm^3 .
- If we want to quantify individual parts of our sample, these parts should be **homogeneous within the analytical volume!**

Setting the scene

What is XRF quantification?

- When a sample is irradiated with X-rays, any irradiated atom in it will begin to fluoresce. → X-ray fluorescence
- Each element has its own characteristic fluorescence energy, and when the XRF spectrum is recorded, it is easy to see which elements are in the sample. → Qualitative analysis
- Quantification is the process to derive the concentrations of the elements from the fluorescence intensities.

Setting the scene

What is XRF quantification?

- The relation between the concentration and the fluorescence intensity of an element is not always easily described.
- Other elements in the sample can lead to **line overlap** or significantly enhance or attenuate the fluorescence, causing the so-called **inter-element effects**.
- With increasing number of elements the correlations become increasingly complex and non-linear.
- Traditionally large sets of **standards** or **reference materials** are used to compare to and compensate for all this non-linearity in complex samples.
- Since almost 70 years* the theoretical foundations are laid out to quantify samples without the use of standards: this is called **fundamental parameter (FP) quantification**.

* J. Sherman, *The theoretical derivation of fluorescent X-ray intensities from mixtures*, Spectrochimica Acta 7 (1955)

Setting the scene

What are the different ways of quantification?

Standard-based measurement

- Without something of known weight, it's not possible to determine the weight of a sample.

Standard-free measurement

- With known properties of the spring and an understanding of the underlying physics you can directly measure the weight of a sample.
- Still, you would check against something of known weight ... just to make sure.

Pictures: <https://de.wikipedia.org/wiki/Balkenwaage> and [/Federwaage](https://de.wikipedia.org/wiki/Federwaage)

Setting the scene

Standard-based measurement

- For precise measurements a set of high-quality reference samples is needed.
- Just like in XRF
 - any damage or alteration of or to the sample will directly impact the quality of the measurement results.
 - The comparison against standards does not depend on the environment.
- Unlike in XRF, a set of reference samples can easily be reproduced or extended for a different range or precision.

Setting the scene

Measurement based on physics

- Just like in XRF, physical processes are fairly well understood.
- First-order processes are easily explained (the gravitational force elongates a spring until its tension compensates that force).
- The mass m then equals the spring constant k of the spring divided by the gravitational acceleration g times the elongation x of the spring.
$$m = \frac{k}{g} x$$
- In order to obtain a higher accuracy, secondary effects need to be taken into account. (local changes of gravity, buoyancy of the object in air, friction, inelastic stress, ...)
- To stay in the picture: the spring constant and the gravitational acceleration at your location would be fundamental parameters, as they are the physical properties that have to be known for the calculation and are tabulated somewhere.

Setting the scene

Measurement based on physics – FP quantification

- There is an equation that allows the calculation of fluorescence intensities I_{fl} produced by a sample of known composition. (first order effects only!)
- This can be used to calculate spectra from samples with assumed compositions.
- It is an iterative process:
guess → *spectrum* → *comparison* → *change guess*
 and ultimately a sample composition can be found that produces a spectrum that matches the measurement.
- μ^* , $\tau_{i,E}$, and $Q_i(E, E_{\text{fl}})$ represent the so-called fundamental parameters, which are probabilities for the physical interactions in the fluorescence process.
- They are known (with varying uncertainties, ~ 10 %)

$$I_{\text{fl}} = C_i \cdot K_i \cdot \int_{E_{\text{abs},i}}^{E_{\text{max}}} I_0(E) \cdot \tau_{i,E} \cdot Q_i(E, E_{\text{fl}}) \cdot \frac{1}{\mu^*} dE$$

μ^*	Attenuation coefficient of the sample
$\tau_{i,E}$	Photoabsorption coefficient
$Q_i(E, E_{\text{fl}})$	Photon production factor
$I_0(E)$	Description of the excitation spectrum
K_i	Instrument parameter
C_i	Concentration(s) of the element(s)

Setting the scene

Different words for quantification

- “Quantification”
What people call a quantification with “acceptable” error margins.
- “Semi-quantitative analysis”
What people call other ways of quantification (error too large).

- Standard-based quantification
Use of standards is essential, accuracy and precision can be very high, if the standards are of sufficient quality.

- FP quantification
Quantification based on the physics and known instrumentation.
 - Standard-supported quantification
Results obtained on standard samples were used to adapt “element sensitivities” according to certain sample systems.
 - Standard-validated quantification
The quantification works without standards, but the instrument itself has been calibrated (usually with pure elements).
 - Standard-less quantification
No standards at all. Knowledge about equipment is as good as it gets today, and the quality of the results is “only” limited by the uncertainties of the fundamental parameters.
 - Standard-free quantification
 - Reference-free quantification

Quantification

Standard-based versus FP quantification

Standard-based

- There have to be some standards (concentration range)
- They have to mirror the sample's structure.
- Origin of reference values?

- If the standards and the samples are equally good, the trueness of the quantification usually is better than FP quantification.

Quantification

Standard-based versus FP quantification

Standard-based

- There have to be some standards (concentration range)
- They have to mirror the sample's structure
- Origin of reference values?

- If the standards and the samples are equally good, the trueness of the quantification usually is better than FP quantification.

FP quantification

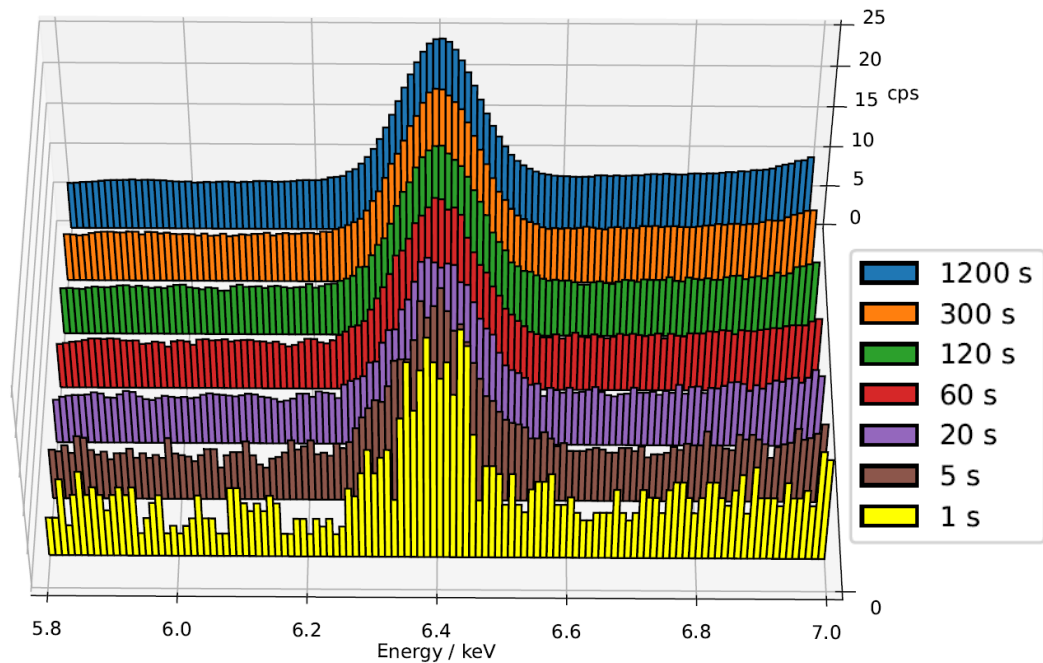

- Flexibility
- Without basing the quantification on standards it's faster to start measuring
- Traceable uncertainties

- Can be validated
- CAN BE calibrated if trustworthy standards are at hand, but works without...

What are prerequisites for quantitative analysis?

Uncertainty of the net peak intensity

- The relative error of counting statistics is $\frac{1}{\sqrt{N}}$
- The more counts, the smaller the relative uncertainty of the measurement → it needs time!

Quantification

What quality to expect?

- Since 1994 ISO 5725-1 defines accuracy as a convolution of trueness and precision.

What's the composition of a sample?

- Does a rock have “a composition”?
- Powders can be considered homogeneous for bulk-XRF, but what part of the hand specimen was crushed and milled?
- Is that part representative?
- Does the initial hand specimen actually describe the site it's been taken from?
- Is it a true sample?
- (Is “the composition” of a rock really a meaningful analytical question?)

Gypsum sample – hand specimen and powder.

What's a known sample?

- As can be seen with almost any reference material the spread of published values is ... significant
- Often there is a mismatch between the carefully selected “preferred values” and the certified compositions.

Is there a perfect standard?

- Milling geo SRMs to < 200 nm gives the resulting powder a glass-like quality.
- There is no measurable inhomogeneity anymore. When pressed, they stick without binder. The grains are smaller than the information depth of the elements! → sounds perfect

Is there a perfect standard?

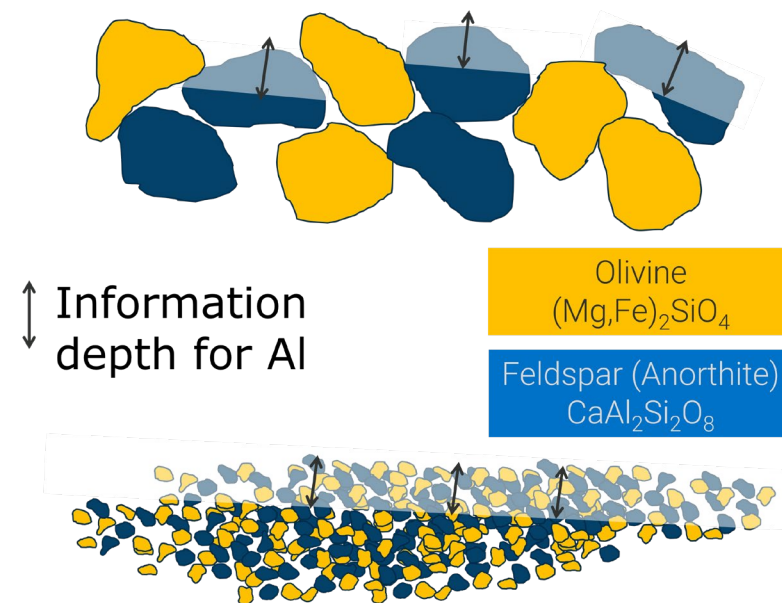

Conventionally milled powder (top row) of basaltic samples exhibits much higher Al intensity than the nano-milled samples (bottom row).

For large particles, effectively none of the detected Al fluorescence has interacted with Fe-rich olivine particles.

→ Only if mineral grains are smaller than the information depths, the inter-element effects are according to the sample's composition.

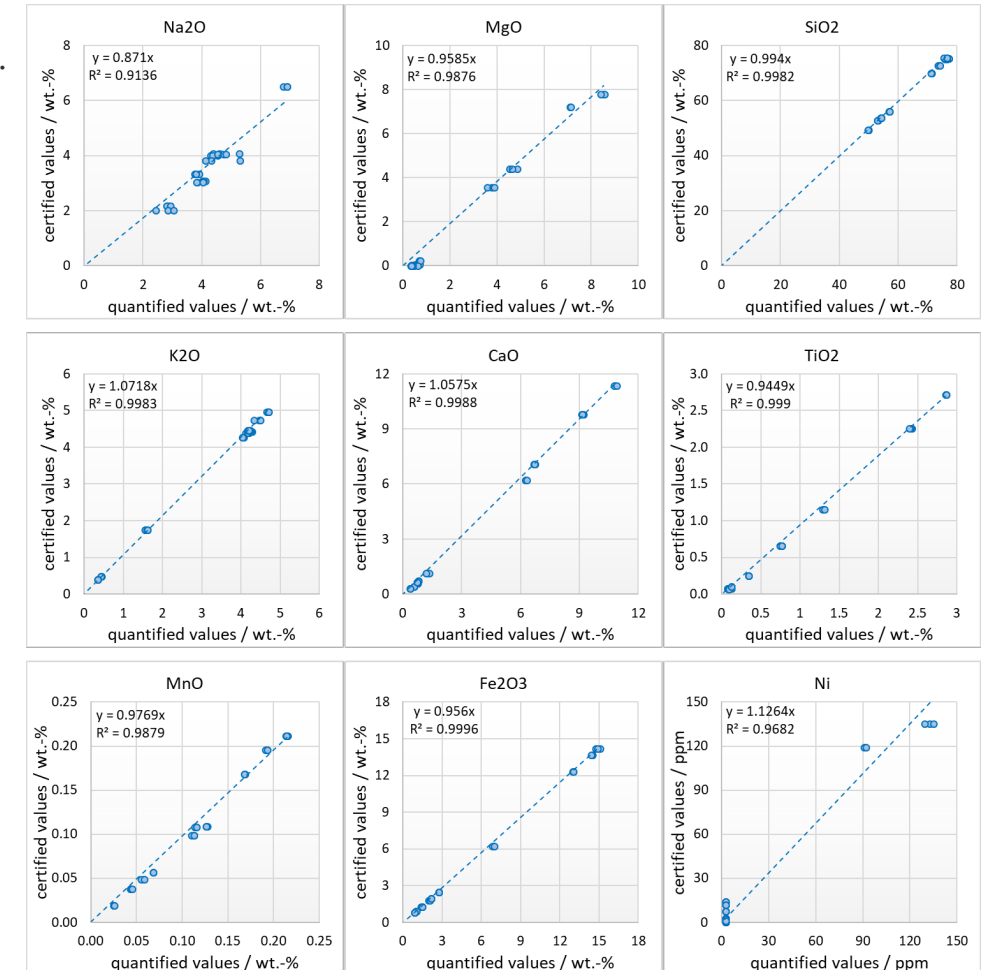

The nano-milled standards can be considered to be ideal for this analytical method ...
But do they reflect the reality (i.e. conventionally milled samples)?

Examples

Major and minor elements in nano-milled geo SRMs

- The recovery rate is very good over a wide concentration range. (especially when considering ~ 50 % “dark matrix”)
- Remember, the quantification assumes a sample composition, based on the selected elements and iteratively calculates all physical effects, like absorption and secondary excitation, and adapts the concentrations until the theoretical spectrum matches the measured one.

- Again, over a wide concentration range there is good linearity between certified values and FP quantification.
- Inter-element effects are “taken care of” by the quantification, making this relation very linear and easy to calibrate.

Examples

Mn, Cr, Fe, Ni in stainless steels

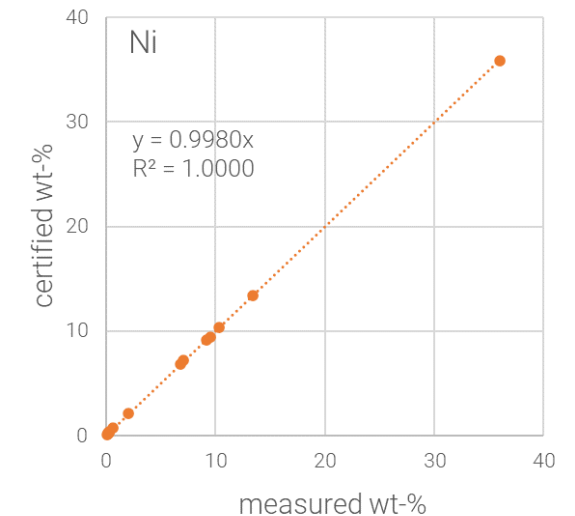

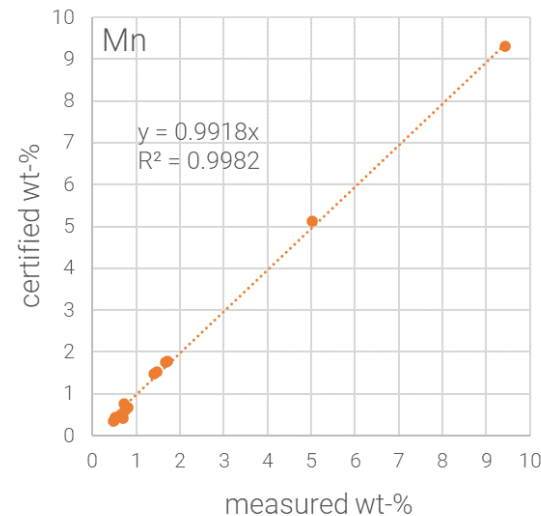

- In a stainless steels, there are 3 elements in high concentrations that influence each other significantly: Cr, Fe, and Ni do absorb and enhance each others fluorescence lines.
- Even though the measured intensities scatter quite a bit, the concentrations have a $R^2 = 1$

Examples

Mn, Cr, Fe, Ni in stainless steels

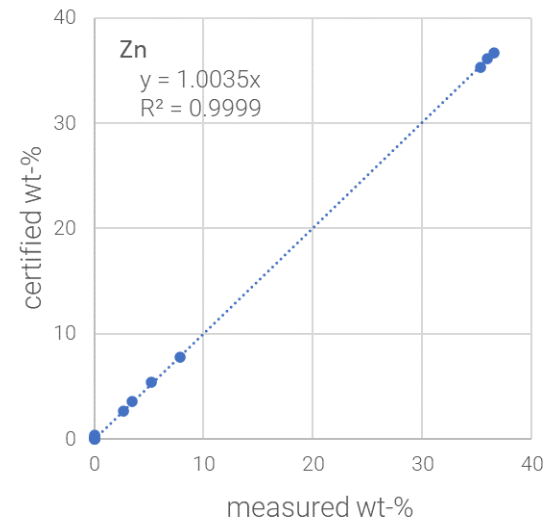

- In stainless steels the precision of FP quantification is very high.
- In metals diffraction peaks can cause wrong values for minor elements.
- The trueness can be improved using one sample of known composition.

Examples

Cu, Zn, Sn, and Pb in copper-alloys

- In Cu alloys the quantification, again, takes care of the complex inter-element effects.
- Over the whole concentration range, there is very nice correlation.
...for most elements
- Note that Lead has a $R^2 = 1$ but is consistently off by 30 %

Examples

Exsolutions in copper-alloys

- Cu alloys are heterogeneous on a scale that micro-XRF notices!
- Lead forms small “islands” → most Pb radiation comes from a Pb-rich part of the sample.

Examples Exsolutions in copper-alloys

- All elements in the alloy form exsolutions, but to different extent.
- Larger scale measurements will not notice the heterogeneities (see scale).
- Luckily it's the same for standards
 - The effect is automatically corrected for by standard-based quantification!

Examples

Trace elements and crystal zonation

Atacamite: Individual Crystal Trace Element Zonation
 Key element concentrations correspond to LA-ICP-MS Results

Sapphires: Individual Crystal Trace Element Zonation

Today's quality of FP quantification ... when applied to ideal samples

- In ideal samples, trace element quantification is even more stable:

Today's quality of FP quantification

Where is the limit for result quality?

- The same quantification algorithm can be applied to copper alloys, stainless steels, mineral samples, either carbonates, sulfates or oxides, ores, layered samples, glasses, ceramics.
- The recovery rate may not be 1 but the correlation is linear, thus the methods can easily be type-calibrated.
- One trustworthy standard can be enough, since all the results fall on one line.

- Usually the quality of the results is limited by the sample itself much more than by the FP algorithm
 - nano-milled powders and glasses are ideal samples and give “perfect” correlations.

- So ... How much help can standards be to improve the quality of this approach?

Using reference samples

Gold References from different manufacturers

- Overall, the correlation looks good over the whole concentration range and for different sources for the reference materials.
- But: the quality of some of these standards (or their certified values) is not sufficient to calibrate FP quantification.
- Some examples:

Using reference samples

Reference values based on other XRF

- Given the overall performance of FP quantification, it is save to assume that there is something wrong with these certified values.
- According to the supplier, the reference values were themselves obtained by XRF measurements.
- The reference values are stated with a precision of 2 post-comma-digits ...

FP Quantification

Today's limits of the algorithm

- The uncertainties of the fundamental parameters:
 - depending on the element and the spectral range they can be as high as 40 % (for very light elements), but usually are well below 5 %.
- The instrument parameter is of great importance:
 - Each individual component in the beam path contributes to the overall uncertainties.
 - The uncertainty introduced by the geometry is significant.

$$I_{\text{fl}} = C_i \cdot K_i \cdot \int_{E_{\text{abs},i}}^{E_{\text{max}}} I_0(E) \cdot \tau_{i,E} \cdot Q_i(E, E_{\text{fl}}) \cdot \frac{1}{\mu^*} dE$$

μ^*	Attenuation coefficient of the sample
$\tau_{i,E}$	Photoabsorption coefficient
$Q_i(E, E_{\text{fl}})$	Photon production factor
$I_0(E)$	Description of the excitation spectrum
K_i	Instrument parameter
C_i	Concentration(s) of the element(s)

Summary

- Micro-XRF is a method designed to analyse and understand samples which are heterogeneous ($> 50 \mu\text{m}$).
- The accuracy of FP quantification is often higher than the element variations in heterogeneous samples.
- Quantifying each individual (homogeneous) part of the sample based on standards, is a huge effort.
 - It takes time to select the individual quantification methods.
 - It takes huge amounts of time to monitor the validity of all the different calibrations.(What is the analytical benefit of a high precision quantification of tiny areas in a heterogeneous sample?)
- FP quantification puts the quantified values on a straight correlation line. → relative changes easily assessable
- FP quantification is accurate enough to validate the quality of standards used for calibration.
- Trustworthy standards CAN be used to calibrate the quantification and increase the accuracy.
- Using small sets of standards to type-calibrate is much more time- and cost-efficient than properly calibrating the instrument geometry and its individual components (windows, detector, lens, a.s.o.).

Innovation with Integrity

Thank you!
